Introduction to inheritance

What Is Inheritance?

Concept 1

Inheritance allows a new class to be based on an existing class. The new class inherits all the member variables and functions (except the constructors and destructor) of the class it is based on.

All insects have certain characteristics.

Insect

In addition to the common insect characteristics, the bumblebee has its own unique characteristics such as the ability to sting.

In addition to the common insect characteristics, the grasshopper has its own unique characteristics such as the ability to jump.

## Inheritance and the "Is a" Relationship

When one object is a specialized version of another object, there is an "is a" relationship between them. For example, a grasshopper is an insect. Here are a few other examples of the "is a" relationship.

- A poodle *is a* dog.
- A car *is a* vehicle.
- A tree *is a* plant.
- A rectangle *is a* shape.
- A football player *is an* athlete.

Inheritance involves a **base class** and **a derived class**.

- The base class is the general class and the derived class is the specialized class.
- The derived class is based on, or derived from, the base class.

C++ Syntax of Derivation

Syntax

```cpp
class <Derived Class> : <Type Of Inheritance> <Base class>
{
public:
    <public attributes/functions>
private:
    <private attributes/functions>
};
```

Class Hierarchies

Concept 2

A base class can also be derived from another class.

- Sometimes it is desirable to establish a hierarchy of classes in which one class inherits from a second class, which in turn inherits from a third class
- In some cases, the inheritance of classes goes on for many layers.

Hierarchical organization of concepts

- A group of concepts is divided into sub-groups according to some criterion.
- We should use only one criterion at a time to classify a group of concepts.

# Protected Members and Class Access

Concept 3

Protected members of a base class are like private members, but they may be accessed by derived classes. The base class access specification determines how private, public, and protected base class members are accessed when they are inherited by the derived classes.

Types of inheritance (in C++)

- There are 3 types of inheritance in C++:
  - **public inheritance**: public and protected of the base class become public and protected of the derived class.
  - **protected inheritance**: public and protected of the base class become protected of the derived class.
  - **private inheritance**: public and protected of the base class become private of the derived class.
- **Notes**: from now on, if there is no mention of what type of inheritance, it means public inheritance

Member functions inheritance

- Member functions of the base class are inherited in the derived class, except:
  - Constructors
  - Destructors
  - Assignment operators

Workshop

Order of Construction/Deconstruction

Concept 4

The base class's constructor is called before the derived class's constructor. The destructors are called in reverse order, with the derived class's destructor being called first.

When a new object of a derived class is created:

- The constructor of the base class is invoked first.
- Then, the constructor of the derived class is invoked.
- In the constructor of the derived class, we can specify which constructor of the base class is called. Otherwise, the default constructor of the base class will be invoked.

When an object of the derived class finishes its lifespan:

- The destructor of the derived class is invoked first.
- Then, the destructor of the base class is called later.

Base Class Initialization

- Using **initialization lists** and in invoking the appropriate base class
  constructor via the constructor of the derived class

```
class Base {
public:
   Base(int SomeNumber) { // overloaded constructor
      // Do something with SomeNumber
   }
};
class Derived: public Base {
public:
   Derived(): Base(25) { // instantiate class Base with
                         // argument 25
      // derived class constructor code
   }
};
```

Aggregation

Workshop

Derived Class Overriding Base Class' Methods

- Sometimes, we need to "re-define" the member functions of a base class in a derived class. It can be done by implements the same functions in the class Derived with the same return values and signatures as in the class Base it inherits from

Notes

This re-definition will **hide other overloading member functions** of this function from the base class.

Invoking Overridden Methods of a Base Class

- If we want to be invoke Fish::Swim(), we need to use the scope resolution operator (::)

```
int main() {
   ...
   myDinner.Fish::Swim();
   ...
}
```

- If our specialized implementations in Tuna:Swim() and Carp::Swim() need to reuse the base class' generic implementation of Fish::Swim(), we use the scope resolution operator (::)

```
class Carp: public Fish {
public:
   Carp(): Fish(true) {}
   void Swim() {
      cout << "Carp swims real slow" << endl;
      Fish::Swim();  // use scope resolution operator::
   }
};
```

Problem with re-definition

```cpp
class Base {
public:
  void test() {...}
  void test(int) {...}
  void test(int, int) {...}
};
class Derived : public Base {
public:
  void test(int) {...}
};
```

```cpp
int main() {
  Derived obj;
  int x, y;
  ...
  obj.test(x);    // OK
  obj.test(x, y); // compile error
}
```

- Solution 1: Use the scope resolution operator ::
- Solution 2: Use the using keyword in class Derived to unhide other overloaded methods
- Solution 3: Override all overloaded methods

The Problem of Slicing

- What happens when a programmer does the following?

```
Derived objectDerived;
Base objectBase = objectDerived;
```

- Or, alternatively, what if a programmer does this?

```
void FuncUseBase(Base input);
...
Derived objectDerived;
FuncUseBase(objectDerived);
```

- The compiler copies only the Base part of objectDerived—that is, not the complete object—rather than only that part of it that would fit Base.

Concept 5

The unwanted reduction of the part of data that makes the Derived a specialization of Base is called *slicing*.

The Problem of Slicing (cont.)
Caution

To avoid slicing problems, **don't pass parameters by value**.

Assignment operator

- Assignment operator is not inherited from the base class. To implement the assignment operator for the derived class:
    - First, calling the assignment operator of the base class to assign data members of the base class .
    - Then, implement the assignment for data member of the derived class part.

```
Derived& operator= (const Derived& CopySource)
{
   if(this != &copySource) { // do not copy itself
      // the base class copy
      Base::operator=(CopySource)
      // the derived class copy
   }
   return *this;
}
```

Aggregation 🧠⚙️

Concept 7

Aggregation occurs when a class contains an instance of another class.

- When an instance of one class is a member of another class, it is said that there is a "has a" relationship between the classes.
- For example, the relationships that exist among the `Course`, `Instructor`, and `TextBook` classes can be described as follows:
  - The course *has an* instructor.
  - The course *has a* textbook.

Aggregation

```
┌─────────────────────────────────────────────────────────────┐
│                           Course                              │
├─────────────────────────────────────────────────────────────┤
│ ☐ courseName : string                                         │
│ ☐ instructor : Instructor&                                    │
│ ☐ textBook : TextBook&                                        │
